Tight binding electrons on a honeycomb lattice are described by an effective Dirac theory at low energies. Lowering symmetry by an alternate ionic potential (Δ) generates a single-particle gap in the spectrum. We employ the dynamical mean field theory (DMFT) technique, to study the effect of on-site electron correlation (U) on massive Dirac fermions. For a fixed mass parameter Δ , we find that beyond a critical value $U_{c1}(\Delta)$ massive Dirac fermions become massless. Further increasing U beyond $U_{c2}(\Delta)$, there will be another phase transition to the Mott insulating state. Therefore the competition between the single-particle gap parameter, Δ , and the Hubbard U restores the semi-metallic nature of the parent Hamiltonian. The width of the intermediate semi-metallic regime shrinks by increasing the ionic potential. However, at small values of Δ , there is a wide interval of U values for which the system remains semi-metal.

INTRODUCTION

The single-particle spectrum of excitations in graphene [1] can be very accurately described by a tight-binding model involving hopping between the localized p_z orbitals of neighboring carbon atoms [2]. The low-energy sector of such Hamiltonian will be described by a 2+1 dimensional Dirac theory [3]. Starting from this point, many perturbations can be imagined and/or fabricated to modify the spectrum of Dirac electrons [4]. From applications point of view, it is important to open up a gap in the spectrum by lowering the symmetry of the nearest neighbor tight-binding Hamiltonian. For example the substrate can induce a sub-lattice symmetry breaking, e.g. by adding an alternate ionic potential of strength Δ , which immediately leads to a charge gap of magnitude 2Δ in the spectrum of single-particle excitations and renders the Dirac electrons massive [5, 6] the ground state of which will be a trivial band insulator (BI). Recent *ab-initio* estimates of the strength of the Hubbard U in graphene suggests that the on-site Coulomb repulsion is quite remarkable, ~ 10 eV [7]. Since this value is expected to be a local property of p_z orbitals in carbon atoms, one do not expect the above value of U to be much different when the Dirac fermions of the underlying honeycomb lattice acquire a mass due to extrinsic effects, such as substrate, binding with ad-atoms such as hydrogen [8], etc. Therefore it is important to consider the competition between the single particle gap parameter Δ and the Hubbard parameter U on top of a semi-metallic state at half-filling. On the strongly correlated limit, when the Hubbard energy scale dominates over the ionic potential, i.e. $U \gg \Delta$, the system will be a Mott insulator (MI) where the charge fluctuations become costly because of no-double-occupancy constraint imposed by large U , while in the opposite limit where Δ dominates over U , the system can be described in terms of an effective massive Dirac theory. The purpose of this paper is to show that short range many-body Coulomb interaction U can transform massive Dirac fermions into massless

ones.

The threefold coordination of carbon atoms on the honeycomb lattice of graphene is the basic mathematical reason for emergence of cone-like dispersion in graphene which is responsible for semi-metallic properties. If the dimension and/or coordination number were different, the parent one-band tight-binding Hamiltonian would at half-filling describe a metal. Previous DMFT study by Garg and coworkers predicts that for metallic parent Hamiltonians, the intermediate phase will be a metal [9], i.e. the competition between Hubbard and ionic terms in a metal, restores the metallic state. One may ask the same question for semi-metallic (Dirac) systems: What would be the result of competition between the Hubbard and ionic terms in a semi-metal? Would the intermediate phase be a metal? Or the competition between the Hubbard and ionic terms –both of which would individually drive the system towards insulating behavior – will give way for the semi-metallic behavior?

To tackle this question, the dynamical mean field theory (DMFT) is a suitable and powerful method [10], which is capable of handling Hubbard interaction in a proper way. This approximate technique becomes exact in the limit of infinite coordination numbers [10, 11] which can be formally incorporated by assumption of a higher dimensional generalization of various lattices [10, 12]. For lower coordination number, the local (k -independent) self-energy employed in the DMFT becomes only an approximate description. Hence, the most significant drawback of the method is expected to be the underestimation of the spatial quantum fluctuations [13–15]. Therefore the values of the critical parameters obtained from a simple DMFT on the honeycomb geometry maybe overestimated [16]. However, the overall picture emerging from this numerically powerful method is expected to hold even when more sophisticated methods, such as cluster DMFT [17], Gutzwiller projection [18] alternative techniques such as quantum Monte Carlo [19] or slave-particle [20] schemes are employed. Since in this work we are

not interested in fine spectral details, the lack of k -resolution we believe will not affect the central conclusion of the paper, namely that the semi-metallic behavior is restored when Hubbard and ionic potential compete.

The ionic-Hubbard model has been studied extensively in one dimension [21], and two dimensions, and the nature of interim phase has been debated [22]. In addition to various low-dimensional techniques employed to study such model, the DMFT technique has also been employed to study the nature of intermediate phase of this model for metallic parent systems [9, 23]. In Ref. [9] the authors implemented DMFT for the Bethe lattice and found that by increasing U for fixed Δ , the system undergoes two phase transition: First from band insulator into metallic phase, and second from metal into Mott insulator phase [9]. However in Ref. [23] they used almost the same method and find coexistence insulator phase region for some Δ, U [23].

MODEL AND METHOD

The ionic-Hubbard Hamiltonian on the honeycomb lattice with two atoms in same unit cell is given by,

$$H = -t \sum_{i \in A, j \in B} [c_{i,\sigma}^\dagger c_{j,\sigma} + h.c.] + \Delta \sum_{i \in A} n_i - \Delta \sum_{i \in B} n_i + U \sum_i n_{i\uparrow} n_{i\downarrow} - \mu \sum_i n_i, \quad (1)$$

where t is the nearest neighbor hopping, Δ denotes the ionic potential which alternates sign between site in sub-lattice A or B . The Hubbard U stands for the repulsion potential between two electrons with opposite spins in i th site of the lattice. The chemical potential is $\mu = U/2$ at half filling and so the average filling factor is $\frac{\langle n_A \rangle + \langle n_B \rangle}{2} = 1$. The model for $t > 0$ and noninteracting limit $U = 0$, represents a band insulator, with energy gap $E_{gap} = 2\Delta$. The average filling factors at half-filling will become $\langle n_A \rangle = 0, \langle n_B \rangle = 2$. For $U \gg \Delta$, the system is in the Mott insulator phase with $n_A = n_B = 1$ [24]. In the intermediate region, a flow-equation analysis shows that at some energy scale, the ionic and Hubbard terms are expected to cancel each other's effect [24]. From this angle we expect the character of the parent Hamiltonian (i.e. the hopping term only) to dominate the nature of the ground state. Therefore for metallic parent Hamiltonians we expect the intermediate phase to be a metal [9, 24], while for semi-metallic parent Hamiltonian as will be shown in the following, the semi-metallic character will be restored and the massive Dirac fermions will become massless. as a result of increasing the Hubbard U .

To formulate the DMFT machinery for semi-metallic parent system, consider a parent tight-binding Hamiltonian on the honeycomb lattice to be in the paramagnetic phase. The interaction Green's function in the bipartite lattice acquires a

matrix form as,

$$G(\vec{k}, \omega^+) = \begin{pmatrix} \zeta_A(\vec{k}, \omega^+) & -\epsilon(\vec{k}) \\ -\epsilon(\vec{k}) & \zeta_B(\vec{k}, \omega^+) \end{pmatrix} \quad (2)$$

where $\vec{k}$ is the momentum vector in first Brillouin zone, $\epsilon(\vec{k})$ is the energy dispersion for the honeycomb lattice [2], and $\zeta_{A(B)} = \omega^+ \mp \Delta + \mu - \Sigma_{A(B)}(\omega^+)$ with $\omega^+ = \omega + i0^+$. In DMFT approximation the self-energy, $\Sigma_\alpha(\omega^+)$ is local [10], i.e. the self-energy matrix is diagonal and independent of $\vec{k}$. Therefore the off-diagonal elements vanish. Hence the local Green's function corresponding to sub-lattice $\alpha = A, B$ can be written as, $G_\alpha(\omega^+) = \sum_{\vec{k}} G_{\alpha\alpha}(\vec{k}, \omega^+)$ which simplifies to [9],

$$G_\alpha(\omega^+) = \zeta_{\bar{\alpha}}(\omega^+) \int_{-\infty}^{\infty} d\epsilon \frac{\rho_0(\epsilon)}{\zeta_A(\omega^+) \zeta_B(\omega^+) - \epsilon^2} \quad (3)$$

where $\alpha = A(B)$, $\bar{\alpha} = B(A)$ and $\rho_0(\epsilon)$ is the bare DOS of the honeycomb lattice [2].

We start with an initial guess for the filling factor and self-energy [9]. Then we determine host Green's function from the Dyson's equation $\mathcal{G}_{0\alpha}^{-1}(\omega^+) = G_\alpha^{-1}(\omega^+) + \Sigma_\alpha(\omega^+)$. Afterwards, we solve impurity problem and find $\Sigma_\alpha(\omega^+) = \Sigma_\alpha[\mathcal{G}_{0\alpha}(\omega^+)]$. In this step we use iterated perturbation theory (IPT) as impurity solver [10]. The iteration of these steps continues until convergence is reached. After convergence, we calculate the density of states given by $\rho_\alpha(\omega) = -\sum_{\vec{k}} \text{Im Tr}[G_\alpha(\vec{k}, \omega^+)]/\pi$. The particle-hole symmetry at half-filling leads to $\rho_A(\omega) = \rho_B(-\omega)$, for the DOS of the two sub-lattices. The total DOS for the honeycomb lattice is eventually obtained via $\rho(\omega) = \rho_A(\omega) + \rho_B(\omega)$.

RESULTS AND DISCUSSION

FIG. 1: (Color online) The density of state for honeycomb lattice in ionic-Hubbard model is plotted for $U = 0.1t, 7t, 11t$ and $\Delta = 0.1t$ from down to up. Between band and Mott insulator phase the semi-metal phase exist as the middle phase.

In Fig. 1, we have shown the converged results for three typical values of U at a constant $\Delta = 0.1t$. As can be seen in

FIG. 2: (Color online) The zoom in the low energy part of the DOS for $U = 0.1t, 7t, 11t$ at fixed $\Delta = 0.1t$. By increasing U , the single particle gap closes to restore the semi-metallic phase, which is then followed by a SMIT.

this overall picture which covers the whole range of energies in the bandwidth, for small values of U , we have simple band gap in the spectrum which has single-particle character. As U increases, spectral weight is transferred to higher energies to form upper and lower Hubbard bands. The striking feature in Fig. 1 is that, despite the formation of Hubbard bands at larger values of U , the overall shape of the low-energy spectral features resemble that of the parent Hamiltonian. The DOS around the Fermi level is V shaped at energy scales above $\sim \Delta$, and the van-Hov singularity arising due to the saddle point in the band structure moves towards lower energies.

In Fig. 2 we have zoomed in the lowest energy scales around the Fermi level. As can be clearly seen in this figure, increasing U eventually closes the single-particle gap, and restores the linear DOS at all low-energy scales, including those below $\sim \Delta$, and renders the system semi-metallic. To our knowledge, *this is a rare instant where many-body interactions of relativistic fermions effectively removes their mass*

FIG. 3: (Color online) By increasing U the slope of DOS in the intermediate SM region changes. This in turn means an increase in the Fermi velocity of electrons. This figure corresponds to $\Delta = 0.1t$.

and makes them massless. By further increasing U , up to $11t$, the spectral transfer to upper and lower Hubbard bands becomes more and more (Fig. 1), while at the same time a Mott-Hubbard gap appears around the Fermi surface as in Fig. 2. Therefore at a fixed value of Δ , as one increases U , there will be a phase transition at U_{c1} to the parent semi-metallic phase, followed by another phase transition at larger U_{c2} to the Mott insulating phase. The intermediate phase is characterized by a strictly linear DOS in the low-energy scales, which qualifies the intermediate phase for an effective Dirac theory. Note that the Fermi velocity in the intermediate effective 2+1 Dirac theory is renormalized with respect to the effective Dirac theory of the parent Hamiltonian. In Fig. 3, we show converged results for three typical U values in the intermediate regime which indicate the decrease in the Fermi velocity of the intermediate Dirac liquid phase as a function of U which ultimately leads to a SMIT [13].

Repeating such calculations for a range of ionic potential Δ , we map out the phase diagram for the ionic Hubbard model on the honeycomb lattice, the boundaries of which are represented by blue and red lines in Fig. 4. First of all for $\Delta \approx 0$, the width of the band insulating (BI) phase diminishes which is equivalent to $U_{c1} \approx 0$, and there will be only one phase transition separating SM and MI phases [13–15]. Note that the vertical axis denotes values of U/W , where W is the bandwidth of the parent Hamiltonian. As can be seen in Fig. 4, by increasing Δ , the SM region becomes narrower, and beyond $\Delta/t \sim 0.5$ – the energy scale up to which the Dirac cone linearization holds – the red and blue boundaries merge. Beyond this point, the phase transition will be essentially between the BI and MI phases.

For comparison in Fig. 4 we have also reproduced the data from Ref. [9] for a metallic parent Hamiltonian with Bethe lattice DOS. One interesting difference between the intermediate region on the honeycomb and Bethe lattice is that the in the former case, the ground state of the parent Hamiltonian (SM) occupies a much larger region in the two dimensional space of $(\frac{\Delta}{t}, \frac{U}{W})$. This could be interpreted as the robustness of the parent phase of the Dirac electrons compared to Schrodinger electrons when an ionic and Hubbard energy scales compete. One more conclusion could be drawn from Fig. 4 is that if we imagine a horizontal line at a constant $U_g/W \sim 0.5 - 0.7$ which maybe relevant to graphene [7], it can be seen that for a range of $\Delta/t \sim 0.04 - 0.05$, the system still remains in the SM phase. For a reasonable estimate of $t \sim 2.7 - 3$ eV, this implies that, graphene can remain SM despite a symmetry breaking ionic potential of strength $\Delta \sim 110 - 150$ meV. Such a single-site DMFT may have overestimated the upper boundary $U_{c2}(\Delta)$ [16]. Improving on this calculations by e.g. cluster extension of DMFT is expected to push the upper boundary down, and hence our estimate of the tolerance $\Delta \sim 110 - 150$ meV is not expected to change much.

Normally the gap magnitudes in gapped graphene samples are assumed to satisfy $E_{\text{Gap}}^{(0)} = 2\Delta$. However this picture holds when one completely ignores the many-body effects. Hence we have used the superscript “0” to emphasize that it is

FIG. 4: (Color online) The DMFT phase diagram of the ionic-Hubbard model on the honeycomb lattice. Band insulating phase (BI) and Mott insulating phase (MI) are separated by a semi-metallic phase (SM). For comparison we have also given the similar phase diagram obtained for metallic parent Hamiltonian [9]. The Hubbard energy scales in both plots are reported in units of bandwidth W .

FIG. 5: (Color online) The E_{Gap} in units of t as a function of U/t for $\Delta = 0.1t$ is plotted. Presence of non-zero U strongly modifies the actual gap, compared to the "non-interacting gap" 2Δ .

"non-interacting" gap. In Fig. 5 we plot the actual spectral gap as a function of U for a fixed value of $\Delta = 0.1t$. As can be seen the actual (interacting) gap strongly depends on the interaction parameter U in both band- and Mott-insulating phases. In particular the value of gap corresponding to $U \sim 4t$ which is relevant to graphene, at $\Delta = 0.1t \sim 280\text{meV}$ is expected to be less than half of the non-interacting estimate. Hence without proper account of the on-site correlations [7], the estimates of Δ based on the observation of E_{Gap} is expected to be about a factor of two underestimated.

SUMMARY AND DISCUSSIONS

We studied the ionic-Hubbard model on honeycomb lattice by DMFT method, and we found the system under goes two phase transition by increasing U for $\Delta > 0$. For $U < U_{c1}(\Delta)$ the system is in band insulator phase whose effective low-

energy theory is 2+1D massive Dirac theory. For $U_{c1}(\Delta) < U < U_{c2}(\Delta)$ region the competition between U and Δ energy scales restores the semi-metallic character of the parent Hamiltonian and makes them massless Dirac fermions. Ultimately, for $U > U_{c2}(\Delta)$ the strong correlations transform the intermediate SM to a Mott insulator [13]. Beyond $\Delta \sim 0.5t$, the upper and lower critical values approach each other and the semi-metallic region will be so narrow that it will disappear. This theoretical study has implications for gapped graphene samples. The observed values of spectral gap is always below the "non-interacting" value of 2Δ . The strong renormalization of the gap magnitude is not the only manifestation of the Hubbard correlations U . It also strongly influences other spectral features such as the life-time of quasi particles, e.g. in hydrogenated graphene [25].
